### BOX 5

Why are some machine learning systems 'black boxes'?

A neural network is an approach to machine learning in which small computational units are connected in a way that is inspired by connections in the brain. These systems may consist of many layers of neurons: the base layer receives an input from an external source, then each layer beyond it detects patterns in activity from the neurons in the layer beneath, integrates these inputs, and then passes a signal to the next layer<sup>[9]</sup>. In this way, signals can be passed through many layers, before reaching a top layer where a decision about the input is made. So, if the initial input is an image, the initial signals might come from the pixels of the image, and the top-level decision might be what object is in the image. As such systems learn from data, they strengthen or weaken synaptic connections to make their outputs more accurate.

This approach to processing data means that information across the neural network is highly dispersed, with complicated patterns of connection strength between units, and with potentially many thousands of layers of units. The result is the so-called 'black box' issue: these systems can create highly accurate results, but it is difficult to explain why a result has been obtained.

However, not all machine learning methods use this approach, and alternative approaches can be more readily interpreted.

This is directly related to this topic

Learning

References

- ▶ Notions of algorithm, effective procedure, computability. [Tur36].

*Although the class of computable numbers is so great, and in many ways similar to the class of real numbers, it is nevertheless enumerable. In §8 I examine certain arguments which would seem to prove the contrary. By the correct application of one of these arguments, conclusions are reached which are superficially similar to those of Gödel [1]. These results have valuable applications. In particular, it is shown (§11) that the Hilbertian Entscheidungsproblem can have no solution. In a recent paper Alonzo Church[2] has introduced an idea of “effective calculability”, which is equivalent to my “computability”, but is very differently defined. Church also reaches similar conclusions about the Entscheidungsproblem [3]. The proof of equivalence between “computability” and “effective calculability” is outlined in an appendix to the present paper.*

References

Conditional reasoning is ubiquitous.

Intensively investigated by philosophers: Stalnaker, Lewis, Pearl, and many others.

**There are several conditionals**, “if-sentences”.

*Counterfactuals*: “If Wellington had not beaten Napoleon, someone else would have.”

*Causal*: “If A then causally B.”

*Action*: “If A then B is obtained.”

*Obligation*: “If A then B should (ought to) be the case.”

*General*: “If A then normally B.”

Applications: decision theory, game theory and economics, AI.

Non-classical semantics is sometimes needed: e.g. “If Rome is the capital of Greece, then there are no snakes in Ireland” (Woods, 97)”.
